

COMP0086 Summative Assignment

Nov 14, 2022

Question 1

- (a) Our sample space for images is $\{0, 1\}^D$, where each of our D dimensions can only take binary values, D being the number of pixels in the image. The exponential family best suited on this sample space is the D -dimensional multivariate Bernoulli distribution because it shares the same sample space. On the other hand, a D -dimensional multivariate Gaussian has the sample space \mathbb{R}^D , which does not match the sample space of our data. To match our data sample space, we might have to define an additional mapping between our data and model spaces, adding unnecessary complexity. Thus it would be inappropriate to model this dataset of images with a multivariate Gaussian.
- (b) For $\{\mathbf{x}^{(n)}\}_{n=1}^N$, a data set of N images, the joint likelihood (assuming images are independently and identically distributed) is the product of N D -dimensional multivariate Bernoulli distributions, one for each image:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p}) = \prod_{n=1}^N P(\mathbf{x}^{(n)} | \mathbf{p})$$

Substituting the D -dimensional multivariate Bernoulli:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p}) = \prod_{n=1}^N \prod_{d=1}^D p_d^{x_d^{(n)}} (1 - p_d)^{1 - x_d^{(n)}}$$

Taking the logarithm of this, we get the log likelihood:

$$\mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p}) = \sum_{n=1}^N \sum_{d=1}^D [x_d^{(n)} \log(p_d) + (1 - x_d^{(n)}) \log(1 - p_d)]$$

Note that since the logarithm is a monotonically increasing function on \mathbb{R}_+ , the maximisers and minimisers of the likelihood do not change. Thus, to solve for the maximum likelihood estimate, \hat{p}_d , we can take the derivative of $\mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p})$ with respect to p_d , the d^{th} element of \mathbf{p} :

$$\begin{aligned} \frac{\partial \mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p})}{\partial p_d} &= \sum_{n=1}^N \left(\frac{x_d^{(n)}}{p_d} - \frac{1 - x_d^{(n)}}{1 - p_d} \right) \\ \frac{\partial \mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p})}{\partial p_d} &= \frac{\sum_{n=1}^N x_d^{(n)}}{p_d} - \frac{\sum_{n=1}^N (1 - x_d^{(n)})}{1 - p_d} \end{aligned}$$

and set the derivative to zero and solve for \hat{p}_d :

$$\begin{aligned}\frac{\sum_{n=1}^N x_d^{(n)}}{\hat{p}_d} - \frac{\sum_{n=1}^N (1 - x_d^{(n)})}{1 - \hat{p}_d} &= 0 \\ \sum_{n=1}^N x_d^{(n)} - \hat{p}_d \sum_{n=1}^N x_d^{(n)} - \hat{p}_d \cdot N + \hat{p}_d \sum_{n=1}^N x_d^{(n)} &= 0 \\ \hat{p}_d &= \frac{1}{N} \sum_{n=1}^N x_d^{(n)}\end{aligned}$$

Moreover, the second derivative with respect to p_d :

$$\frac{\partial \mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p})}{\partial p_d^2} = \frac{-\sum_{n=1}^N x_d^{(n)}}{p_d^2} + \frac{-\sum_{n=1}^N (1 - x_d^{(n)})}{(1 - p_d)^2}$$

For a maximum, we need to show that the second derivative is negative. Since $x_d^{(n)} \in \{0, 1\}$, in the worst case, of $N = 1$, the single pixel $x_d^{(1)}$ must either be white ($\sum_{n=1}^N x_d^{(n)} > 0$) or black ($\sum_{n=1}^N 1 - x_d^{(n)} > 0$) with the other being zero, $\frac{\partial \mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p})}{\partial p_d^2} < 0$ will be guaranteed and \hat{p}_d is a maximum as required for the maximum likelihood estimate.

Because we assume that each pixel is independent (we are taking the product of D one dimensional Bernoulli distributions), we can express the maximum likelihood for \mathbf{p} in vectorised form as $\hat{\mathbf{p}}^{MLE}$:

$$\hat{\mathbf{p}}^{MLE} = \frac{1}{N} \sum_{n=1}^N \mathbf{x}^{(n)}$$

(c) From Bayes' Theorem:

$$P(\mathbf{p} | \{\mathbf{x}^{(n)}\}_{n=1}^N) = \frac{P(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p}) P(\mathbf{p})}{P(\{\mathbf{x}^{(n)}\}_{n=1}^N)}$$

Taking the logarithm:

$$\mathcal{L}(\mathbf{p} | \{\mathbf{x}^{(n)}\}_{n=1}^N) = \mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p}) + \mathcal{L}(\mathbf{p}) - \mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N)$$

Taking the derivative with respect to p_d :

$$\frac{\partial \mathcal{L}(\mathbf{p} | \{\mathbf{x}^{(n)}\}_{n=1}^N)}{\partial p_d} = \frac{\partial \mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p})}{\partial p_d} + \frac{\partial \mathcal{L}(\mathbf{p})}{\partial p_d}$$

where $\frac{\partial \mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N)}{\partial p_d} = 0$ because it doesn't depend on p_d .

We know from (b):

$$\frac{\partial \mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N | \mathbf{p})}{\partial p_d} = \frac{\sum_{n=1}^N x_d^{(n)}}{p_d} - \frac{\sum_{n=1}^N (1 - x_d^{(n)})}{1 - p_d}$$

For the second term $\frac{\partial \mathcal{L}(\mathbf{p})}{\partial p_d}$, we start with $P(\mathbf{p})$, assuming each pixel to have an independent prior:

$$P(\mathbf{p}) = \prod_{d=1}^D P(p_d)$$

Assuming a Beta prior on each p_d :

$$P(\mathbf{p}) = \prod_{d=1}^D \frac{1}{B(\alpha, \beta)} p_d^{\alpha-1} (1-p_d)^{\beta-1}$$

Taking the logarithm:

$$\mathcal{L}(\mathbf{p}) = \sum_{d=1}^D -\log(B(\alpha, \beta)) + (\alpha-1) \log p_d + (\beta-1) \log(1-p_d)$$

Taking the derivative with respect to p_d :

$$\frac{\partial \mathcal{L}(\mathbf{p})}{\partial p_d} = \frac{(\alpha-1)}{p_d} - \frac{(\beta-1)}{1-p_d}$$

Since we are only concerned with p_d , we are only left with a single element of the summation pertaining to p_d .

Combining, we have have an expression for $\frac{\partial \mathcal{L}(\mathbf{p}|\{\mathbf{x}^{(n)}\}_{n=1}^N)}{\partial p_d}$:

$$\begin{aligned} \frac{\partial \mathcal{L}(\mathbf{p}|\{\mathbf{x}^{(n)}\}_{n=1}^N)}{\partial p_d} &= \frac{\sum_{n=1}^N x_d^{(n)}}{p_d} - \frac{\sum_{n=1}^N (1-x_d^{(n)})}{1-p_d} + \frac{(\alpha-1)}{p_d} - \frac{(\beta-1)}{1-p_d} \\ \frac{\partial \mathcal{L}(\mathbf{p}|\{\mathbf{x}^{(n)}\}_{n=1}^N)}{\partial p_d} &= \frac{(\alpha-1) + \sum_{n=1}^N x_d^{(n)}}{p_d} - \frac{(\beta-1) + \sum_{n=1}^N (1-x_d^{(n)})}{1-p_d} \end{aligned}$$

To find the maximum a posteriori (MAP) estimate \hat{p}_d set $\frac{\partial \mathcal{L}(\mathbf{p}|\{\mathbf{x}^{(n)}\}_{n=1}^N)}{\partial p_d} = 0$ and solve:

$$\begin{aligned} 0 &= \frac{(\alpha-1) + \sum_{n=1}^N x_d^{(n)}}{\hat{p}_d} - \frac{(\beta-1) + \sum_{n=1}^N (1-x_d^{(n)})}{1-\hat{p}_d} \\ 0 &= (1-\hat{p}_d)(\alpha-1) + (1-\hat{p}_d) \left(\sum_{n=1}^N x_d^{(n)} \right) - \hat{p}_d(\beta-1) - \hat{p}_d \left(\sum_{n=1}^N (1-x_d^{(n)}) \right) \\ 0 &= (\alpha - \alpha\hat{p}_d + \hat{p}_d - 1) + \left(\sum_{n=1}^N x_d^{(n)} - \hat{p}_d \sum_{n=1}^N x_d^{(n)} \right) - (\hat{p}_d\beta - \hat{p}_d) - \left(\hat{p}_d \cdot N - \hat{p}_d \sum_{n=1}^N x_d^{(n)} \right) \end{aligned}$$

Cancelling the $\hat{p}_d \sum_{n=1}^N x_d^{(n)}$ terms:

$$0 = \alpha - \alpha\hat{p}_d + \hat{p}_d - 1 + \sum_{n=1}^N x_d^{(n)} - \hat{p}_d\beta + \hat{p}_d - \hat{p}_d \cdot N$$

$$0 = \hat{p}_d(2 - \alpha - \beta - N) + \alpha - 1 + \sum_{n=1}^N x_d^{(n)}$$

$$\hat{p}_d = \frac{\alpha - 1 + \sum_{n=1}^N x_d^{(n)}}{(N + \alpha + \beta - 2)}$$

To show that this is a maximum, the second derivative is:

$$\frac{\partial^2 \mathcal{L}(\mathbf{p} | \{\mathbf{x}^{(n)}\}_{n=1}^N)}{(\partial p_d)^2} = \frac{(1 - \alpha) - \sum_{n=1}^N x_d^{(n)}}{(p_d)^2} + \frac{(1 - \beta) - \sum_{n=1}^N (1 - x_d^{(n)})}{(1 - p_d)^2}$$

. For a maximum, we need $\frac{\partial^2 \mathcal{L}(\mathbf{p} | \{\mathbf{x}^{(n)}\}_{n=1}^N)}{(\partial p_d)^2} < 0$ meaning that we need at least one of the strict inequalities $\alpha < 1 - \sum_{n=1}^N x_d^{(n)}$ or $\beta < 1 - \sum_{n=1}^N (1 - x_d^{(n)})$ to be satisfied, where the other can be \leq . The Beta distribution requires $\alpha > 0$ and $\beta > 0$ so this requirement will always be satisfied (in the worst case of a single image, either $x_d^{(1)} = 1$ or $1 - x_d^{(1)} = 1$).

Due to independence of our likelihood and priors for each dimension, we can express the maximum a priori for \mathbf{p} in vectorised form as $\hat{\mathbf{p}}^{MAP}$:

$$\hat{\mathbf{p}}^{MAP} = \frac{\alpha - 1 + \sum_{n=1}^N \mathbf{x}^n}{(N + \alpha + \beta - 2)}$$

(d&e) The Python code for MLE and MAP:

```

src/solutions/q1.py

Displaying the learned parameters:

Figure 1: ML parameters

Figure 2: MAP parameters

Comparing the equations:

$$\hat{\mathbf{p}}^{MLE} = \frac{1}{N} \sum_{n=1}^N \mathbf{x}^{(n)}$$

and

$$\hat{\mathbf{p}}^{MAP} = \frac{\alpha - 1 + \sum_{n=1}^N \mathbf{x}^n}{(N + \alpha + \beta - 2)}$$

As the number of data points increases, $\hat{\mathbf{p}}^{MAP}$ approaches $\frac{1}{N} \sum_{n=1}^N \mathbf{x}^{(n)}$, $\hat{\mathbf{p}}^{MLE}$. This makes sense because as our data set gets bigger, we are less reliant on our prior. However, if a specific pixel in all of the images of our data set are white or all black, the MLE for that pixel would either be 1 or 0. This may not be representative of our intuitions about images, as there should be some non-zero probability of a pixel being black or white. By introducing an appropriate prior we can ensure that the probability of that pixel will never be exactly zero or one. In our case, with a Beta(3,3) prior on each pixel, our parameter values are biased to be closer to 0.5 and to never be at the extremities 0 and 1. We can see this in Figure 2 where the range of our parameters is smaller than the range of Figure 1 and doesn't include zero. Figure 3 visualises $\hat{\mathbf{p}}^{MAP} - \hat{\mathbf{p}}^{MLE}$ and we can see that for likelihoods greater than 0.5 in the MLE, the MAP has a lower value and for likelihoods less than 0.5, the MAP has a higher value, confirming our intuitions.

Figure 3: $\hat{\mathbf{p}}^{MAP} - \hat{\mathbf{p}}^{MLE}$

Priors can also help ensure numerical stability during calculations. The logarithm of zero is negative infinity, so having if the MLE is zero it can be problematic for log-likelihoods calculations whereas MAP can ensure non-zero probabilities. Interestingly, when $\alpha = \beta = 1$, $\hat{\mathbf{p}}^{MLE} = \hat{\mathbf{p}}^{MAP}$. This is when the prior is a uniform distribution and so there is uniform bias on the location of \mathbf{p} and we recover the MLE.

On the other hand, a mis-specified prior can be problematic, as the estimated parameters might be skewed by the prior and not properly represent the underlying data generating process, this can result in parameter estimates that are worse than using the MLE if our data set is limited.

Question 2

When all D components are generated from a Bernoulli distribution with $p_d = 0.5$, we have the likelihood function for model M_1 :

$$P(\mathbf{x}^{(n)}|\mathbf{p}^{(1)} = [0.5, 0.5, \dots, 0.5]^T, M_1) = \prod_{n=1}^N \prod_{d=1}^D (0.5)^{x_d^{(n)}} (0.5)^{1-x_d^{(n)}}$$

When all D components are generated from Bernoulli distributions with unknown, but identical, p_d , we have the likelihood function for model M_2 :

$$P(\mathbf{x}^{(n)}|\mathbf{p}^{(2)} = [p_d, p_d, \dots, p_d]^T, M_2) = \prod_{n=1}^N \prod_{d'=1}^D p_d^{x_{d'}^{(n)}} (1 - p_d)^{1-x_{d'}^{(n)}}$$

When each component is Bernoulli distributed with separate, unknown p_d , we have the likelihood function for model M_3 :

$$P(\mathbf{x}^{(n)}|\mathbf{p}^{(3)} = [p_1, p_2, \dots, p_D]^T, M_3) = \prod_{n=1}^N \prod_{d=1}^D p_d^{x_d^{(n)}} (1 - p_d)^{1-x_d^{(n)}}$$

For each model M_i , we can marginalise out $\mathbf{p}^{(i)}$ to get $P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_i)$:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_i) = \int_0^1 \dots \int_0^1 P(\{\mathbf{x}^{(n)}\}_{n=1}^N | p_d, M_i) P(p_d | M_i) dp_1 \dots dp_D$$

where $d = 1, \dots, D$ and $\{\mathbf{x}^{(n)}\}_{n=1}^N$ is our data set.

Given that the prior of any unknown probabilities is uniform, i.e. $P(p_d | M_i) = 1$. We can simplify:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_i) = \int_0^1 \dots \int_0^1 P(\{\mathbf{x}^{(n)}\}_{n=1}^N | p_d, M_i) dp_1 \dots dp_D$$

For M_1 , we have that all pixels have probability 0.5:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_1) = \int_0^1 \dots \int_0^1 \prod_{n=1}^N \prod_{d=1}^D (0.5)^{x_d^{(n)}} (1 - 0.5)^{1-x_d^{(n)}} d\theta_1 \dots d\theta_D$$

We can remove the integrals and knowing that either $x_d^{(n)}$ or $1 - x_d^{(n)}$ will be 1 and the other zero, we can simplify $(0.5)^{x_d^{(n)}} (1 - 0.5)^{1-x_d^{(n)}}$ to 0.5:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_1) = \prod_{n=1}^N \prod_{d=1}^D (0.5)$$

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_1) = (0.5)^{N \cdot D}$$

For M_2 , we have that all pixels share some probability p_d so we only need to integrate over a single variable p_d :

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_2) = \int_0^1 \prod_{n=1}^N \prod_{d'=1}^D p_d^{x_{d'}^{(n)}} (1 - p_d)^{1-x_{d'}^{(n)}} dp_d$$

Changing the products to sums:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_2) = \int_0^1 p_d^{\sum_{n=1}^N \sum_{d'=1}^D x_{d'}^{(n)}} (1 - p_d)^{\sum_{j=1}^N \sum_{d'=1}^D 1 - x_{d'}^{(n)}} dp_d$$

Rewriting:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_2) = \int_0^1 (p_d)^K (1 - p_{d'=1})^{N \cdot D - K} dp_d$$

where $K = \sum_{n=1}^N \sum_{d'=1}^D x_{d'}^{(n)}$.

This integral is the beta function:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_2) = \frac{K!(N \cdot D - k)!}{(N \cdot D + 1)!}$$

For M_3 , we need an integral for each p_d :

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_3) = \int_0^1 \dots \int_0^1 \prod_{n=1}^N \prod_{d=1}^D p_d^{x_d^{(n)}} (1 - p_d)^{1 - x_d^{(n)}} dp_1 \dots dp_D$$

We can separate the integrals to only contain the relevant p_d :

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_3) = \prod_{d=1}^D \left(\int_0^1 \prod_{n=1}^N p_d^{x_d^{(n)}} (1 - p_d)^{1 - x_d^{(n)}} dp_d \right)$$

Changing the products to sums:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_3) = \prod_{d=1}^D \left(\int_0^1 p_d^{\sum_{n=1}^N x_d^{(n)}} (1 - p_d)^{\sum_{n=1}^N 1 - x_d^{(n)}} dp_d \right)$$

In this case, we have the product of integrals where each evaluates to a beta function:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_3) = \prod_{d=1}^D \frac{K_d!(N - K_d)!}{(N + 1)!}$$

where $K_d = \sum_{n=1}^N x_d^{(n)}$.

The posterior probability of a model M_i can be expressed:

$$P(M_i | \{\mathbf{x}^{(n)}\}_{n=1}^N) = \frac{P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_i) P(M_i)}{P(\{\mathbf{x}^{(n)}\}_{n=1}^N)}$$

We only have three models, so in this case the normalisation $P(\{\mathbf{x}^{(n)}\}_{n=1}^N)$ can be expressed as a sum:

$$P(M_i | \{\mathbf{x}^{(n)}\}_{n=1}^N) = \frac{P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_i) P(M_i)}{\sum_{i \in \{1, 2, 3\}} P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_i) P(M_i)}$$

Given that $P(M_i) = \frac{1}{3}$ for all $i \in \{1, 2, 3\}$:

$$P(M_i | \{\mathbf{x}^{(n)}\}_{n=1}^N) = \frac{P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_i)}{\sum_{i \in \{1, 2, 3\}} P(\{\mathbf{x}^{(n)}\}_{n=1}^N | M_i)}$$

i	$P(M_i \{\mathbf{x}^{(n)}\}_{n=1}^N)$
1	1E-1924
2	1E-1858
3	$1-(1\text{E-}1924)-(1\text{E-}1858)$

Table 1: Posterior Probabilities

Calculating the posterior probabilities of each of the three models having generated the data in binarydigits.txt using python, we can show the values in the Table 1:

We can see that for models specified to have the same parameter value for all pixels like M_1 is very unlikely with the given data set. This makes sense because it is specifying models where the image is essentially blank (a uniform shade), which is not reflective of our digit images. Moreover, M_1 specifies a specific value of 0.5 for all the parameters whereas M_2 specifies any value for all the parameters as long as it's the same. So the model M_1 is a subset of the models specified in M_2 and we can see this reflected in our probabilities when $P(M_2|\{\mathbf{x}^{(n)}\}_{n=1}^N) > P(M_1|\{\mathbf{x}^{(n)}\}_{n=1}^N)$.

The Python code for calculating the posterior probabilities of the three models:

```

Question 3

- (a) The likelihood for a model consisting of a mixture of K multivariate Bernoulli distributions can be expressed as the product across N data points:

$$P(\{\mathbf{x}^{(n)}\}_{n=1}^N|\theta) = \prod_{i=1}^N P(x_i|\theta)$$

where $\{\mathbf{x}^{(n)}\}_{n=1}^N$ is our data set with $\mathbf{x}^{(n)} \in \mathbb{R}^{D \times 1}$ and $\theta = \{\pi, \mathbf{P}\}$, $\pi = [\pi_1, \dots, \pi_K] \in \mathbb{R}^{K \times 1}$ our mixing proportions ($0 \leq \pi_k \leq 1$; $\sum_k \pi_k = 1$) and $\mathbf{P} \in \mathbb{R}^{D \times K}$ the K Bernoulli parameter vectors with elements p_{kd} denoting the probability that pixel d takes value 1 under mixture component k . We also assume the images are iid and that the pixels are independent of each other within each component distribution.

For each $P(\mathbf{x}^{(n)}|\theta)$:

$$P(\mathbf{x}^{(n)}|\theta) = \sum_{k=1}^K \pi_k \prod_{d=1}^D (p_{kd})^{\mathbf{x}_d^{(n)}} (1 - p_{kd})^{1 - \mathbf{x}_d^{(n)}}$$

The log-likelihood $\mathcal{L}(\mathbf{x}^{(n)}|\theta)$ can be expressed in matrix form:

$$\mathcal{L}(\mathbf{x}^{(n)}|\theta) = \log \sum_{k=1}^K \pi_k \exp \left(\mathbf{x}^{(n)} \log(\mathbf{P}_k) + (1 - \mathbf{x}^{(n)}) \log(1 - \mathbf{P}_k) \right)$$

which can be further vectorised using Python scipy's *logsumexp* operation.

Moreover, the log-likelihood $\mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N|\theta)$ can be expressed:

$$\mathcal{L}(\{\mathbf{x}^{(n)}\}_{n=1}^N|\theta) = \sum_{i=1}^N \left(\log \sum_{k=1}^K \pi_k \exp \left(\mathbf{x}^{(n)} \log(\mathbf{P}_k) + (1 - \mathbf{x}^{(n)}) \log(1 - \mathbf{P}_k) \right) \right)$$

- (b) We know that:

$$P(A|B) \propto P(B|A)P(A)$$

Thus,

$$P(s^{(n)} = k|\mathbf{x}^{(n)}, \pi, \mathbf{P}) \propto P(\mathbf{x}^{(n)}|s^{(n)} = k, \pi, \mathbf{P})P(s^{(n)} = k|\pi, \mathbf{P})$$

where $s^{(n)} \in \{1, \dots, K\}$ a discrete hidden variable with $P(s^{(n)} = k|\mathbf{x}^{(n)}, \pi) = \pi_k$. Note that $P(s^{(n)} = k|\mathbf{x}^{(n)}, \pi) = P(s^{(n)} = k|\mathbf{x}^{(n)}, \pi, \mathbf{P})$ as $s^{(n)}$ isn't dependent on \mathbf{P} .

Let $P(s^{(n)} = k|\mathbf{x}^{(n)}, \pi, \mathbf{P}) \propto P(s^{(n)})$ be the unnormalised responsibility \tilde{r}_{nk} . Using the mixture for component k , π_k and the likelihood function of component k :

$$\tilde{r}_{nk} = \pi_k \prod_{d=1}^D (p_{kd})^{\mathbf{x}_d^{(n)}} (1 - p_{kd})^{1 - \mathbf{x}_d^{(n)}}$$

Normalising across the components:

$$r_{nk} = \frac{\tilde{r}_{nk}}{\sum_{j=1}^K \tilde{r}_{nj}}$$

we have calculated $P(s^{(n)} = k | \mathbf{x}^{(n)}, \pi, \mathbf{P})$ for the E step of an EM algorithm.

Moreover,

$$\log \tilde{r}_{nk} = \log \pi_k + \sum_{d=1}^D \left(\mathbf{x}_d^{(n)} \log(p_{kd}) + (1 - \mathbf{x}_d^{(n)}) \log(1 - \exp(\log(p_{kd}))) \right)$$

and

$$\log r_{nk} = \log \tilde{r}_{nk} - \log \sum_{j=1}^K \exp(\log \tilde{r}_{nj})$$

which can be vectorised as $\log \mathbf{r}_n$ calculated with $\log \pi$ and $\log \mathbf{P}$ using Python scipy's *logsumexp* operation.

(c) We know that the expectation log joint can be expressed:

$$\left\langle \sum_n \log P(\mathbf{x}^{(n)}, s^{(n)} | \pi, \mathbf{P}) \right\rangle_{q(\{s^{(n)}\})} = \sum_{n=1}^N q(s^{(n)}) \log P(\mathbf{x}^{(n)}, s^{(n)} | \pi, \mathbf{P})$$

Let this quantity be E . Each term of E can be expressed:

$$q(s^{(n)}) = \mathbf{r}_n$$

and

$$\log P(\mathbf{x}^{(n)}, s^{(n)} | \pi, \mathbf{P}) = \log[P(\mathbf{x}^{(n)} | s^{(n)}, \pi, \mathbf{P}) P(s^{(n)} | \pi, \mathbf{P})]$$

which is the vectorised version of $\log \tilde{r}_{nk}$ from part (b) so:

$$\log P(\mathbf{x}^{(n)}, s^{(n)} | \pi, \mathbf{P}) = \log(\pi) + \log(\mathbf{P})^T \mathbf{x}^{(n)} + \log(1 - \mathbf{P})^T (1 - \mathbf{x}^{(n)})$$

Combining:

$$E = \sum_n \mathbf{r}_n^T [\log(\pi) + \log(\mathbf{P})^T \mathbf{x}^{(n)} + \log(1 - \mathbf{P})^T (1 - \mathbf{x}^{(n)})]$$

To maximise with respect to π and \mathbf{P} for the M step, we want to take the derivative, set to zero, and solve for $\hat{\pi}$ and $\hat{\mathbf{P}}$.

For the k^{th} element of π :

$$\frac{\partial E}{\partial \pi_k} = \sum_n r_{nk} \frac{1}{\pi_k}$$

The second derivative:

$$\frac{\partial E}{(\partial \pi_k)^2} = \sum_n r_{nk} \frac{-1}{(\pi_k)^2}$$

is always negative because $r_{nk} \geq 0$, $\sum_n r_{nk} = 1$, $\pi_k \geq 0$, and $\sum_n \pi_k = 1$, ensuring a maximum in the next step.

We can calculate the maximiser with:

$$\frac{\partial E}{\partial \pi_k} + \lambda = 0$$

where λ is a Lagrange multiplier ensuring that the mixing proportions sum to unity.

Thus,

$$\hat{\pi}_k = \frac{\sum_n r_{nk}}{N}$$

For the dk^{th} element of \mathbf{P} :

$$\frac{\partial E}{\partial \mathbf{P}_{dk}} = \sum_n r_{nk} \frac{\partial}{\partial \mathbf{P}_{dk}} [\mathbf{x}_d^{(n)} \log \mathbf{P}_{dk} + (1 - \mathbf{x}_d^{(n)}) \log(1 - \mathbf{P}_{dk})]$$

Simplifying:

$$\frac{\partial E}{\partial \mathbf{P}_{dk}} = \sum_n r_{nk} \left(\frac{\mathbf{x}_d^{(n)}}{\mathbf{P}_{dk}} - \frac{1 - \mathbf{x}_d^{(n)}}{1 - \mathbf{P}_{dk}} \right)$$

Similar to Question 1, we can see that taking second derivative, the term in the brackets will always be less than zero and with $r_{nk} \geq 0$ and $\sum_n r_{nk} = 1$, the second derivative will always be negative. This ensures that we have a maximum in the next step.

Setting the derivative to zero:

$$\frac{\sum_n \mathbf{x}_d^{(n)} r_{nk}}{\mathbf{P}_{dk}} - \frac{\sum_n r_{nk} - \sum_n \mathbf{x}_d^{(n)} r_{nk}}{1 - \mathbf{P}_{dk}} = 0$$

Solving for $\hat{\mathbf{P}}_{dk}$:

$$\hat{\mathbf{P}}_{dk} \sum_n r_{nk} - \hat{\mathbf{P}}_{dk} \sum_n \mathbf{x}_d^{(n)} r_{nk} = \sum_n \mathbf{x}_d^{(n)} r_{nk} - \hat{\mathbf{P}}_{dk} \sum_n \mathbf{x}_d^{(n)} r_{nk}$$

Thus,

$$\hat{\mathbf{P}}_{dk} = \frac{\sum_n \mathbf{x}_d^{(n)} r_{nk}}{\sum_n r_{nk}}$$

We have the maximizing parameters for the expected log-joint

$$\arg \max_{\pi, \mathbf{P}} \left\langle \sum_n \log P(\mathbf{x}^{(n)}, s^{(n)} | \pi, \mathbf{P}) \right\rangle_{q(\{s^{(n)}\})}$$

thus obtaining an iterative update for the parameters π and \mathbf{P} in the M-step of EM. For numerical stability, we can compute the maximisation step for the MAP of $\mathbf{P}, \hat{\mathbf{P}}_{dk}^{MAP}$ by solving:

$$\frac{\partial E'}{\partial \mathbf{P}_{dk}} = 0$$

where

$$E' = \sum_{n=1}^N q(s^{(n)}) \log P(\mathbf{P} | \pi, \mathbf{x}^{(n)}, s^{(n)})$$

and from Bayes':

$$\log P(\mathbf{P} | \pi, \mathbf{x}^{(n)}, s^{(n)}) = \log P(\mathbf{x}^{(n)}, s^{(n)} | \pi, \mathbf{P}) + \log P(\mathbf{P}) - \log P(\mathbf{x}^{(n)}, s^{(n)} | \pi)$$

Assuming an independent Beta prior on each pixel of each component:

$$\log P(\mathbf{P}) = \sum_{k=1}^K \sum_{d=1}^D -\log(B(\alpha, \beta)) + (\alpha - 1) \log \mathbf{P}_{dk} + (\beta - 1) \log(1 - \mathbf{P}_{dk})$$

and

$$\frac{\partial \log P(\mathbf{P})}{\partial \mathbf{P}_{dk}} = \frac{(\alpha - 1)}{\mathbf{P}_{dk}} - \frac{(\beta - 1)}{1 - \mathbf{P}_{dk}}$$

Thus, the derivative can be expressed as:

$$\frac{\partial E'}{\partial \mathbf{P}_{dk}} = \sum_n \left(r_{nk} \left(\frac{\partial \log P(\mathbf{x}^{(n)}, s^{(n)} | \pi, \mathbf{P})}{\partial \mathbf{P}_{dk}} + \frac{\partial \log P(\mathbf{P})}{\partial \mathbf{P}_{dk}} \right) \right)$$

Substituting the appropriate expressions:

$$\frac{\partial E'}{\partial \mathbf{P}_{dk}} = \sum_n \left(r_{nk} \left(\frac{\mathbf{x}_d^{(n)}}{\mathbf{P}_{dk}} - \frac{1 - \mathbf{x}_d^{(n)}}{1 - \mathbf{P}_{dk}} + \frac{(\alpha - 1)}{\mathbf{P}_{dk}} - \frac{(\beta - 1)}{1 - \mathbf{P}_{dk}} \right) \right)$$

Simplifying:

$$\frac{\partial E'}{\partial \mathbf{P}_{dk}} = \frac{\sum_n r_{nk}(\alpha - 1 + \mathbf{x}_d^{(n)})}{\mathbf{P}_{dk}} - \frac{\sum_n r_{nk}(\beta - \mathbf{x}_d^{(n)})}{1 - \mathbf{P}_{dk}}$$

For a maximum, we see that we need $\alpha > \mathbf{x}_d^{(n)} - 1$ or $\beta < \mathbf{x}_d^{(n)}$, both of which are satisfied knowing that $\alpha > 0$ and $\beta > 0$. Setting $\frac{\partial E'}{\partial \mathbf{P}_{dk}} = 0$ we can calculate $\hat{\mathbf{P}}_{dk}^{MAP}$:

$$\sum_n r_{nk}(\alpha - 1 + \mathbf{x}_d^{(n)}) - \hat{\mathbf{P}}_{dk} \sum_n r_{nk}(\alpha - 1 + \mathbf{x}_d^{(n)}) = \hat{\mathbf{P}}_{dk} \sum_n r_{nk}(\beta - \mathbf{x}_d^{(n)})$$

$$\hat{\mathbf{P}}_{dk}^{MAP} = \frac{\sum_n r_{nk}(\mathbf{x}_d^{(n)} + \alpha - 1)}{(\alpha + \beta - 1)(\sum_n r_{nk})}$$

As a sense check, we can see when setting $\alpha = 1$ and $\beta = 1$ we recover $\hat{\mathbf{P}}_{dk}^{MLE}$ as we would expect.

(d) Plotting the posterior likelihood as a function of the iteration number:

src/solutions/q3.py

- (e) Running the algorithm a few times starting from randomly chosen initial conditions and visualising the parameters:

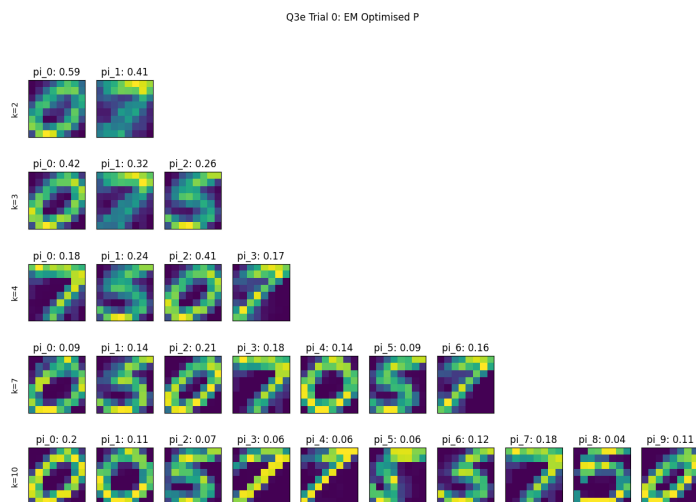

Figure 7: EM optimised parameters: Trial 0

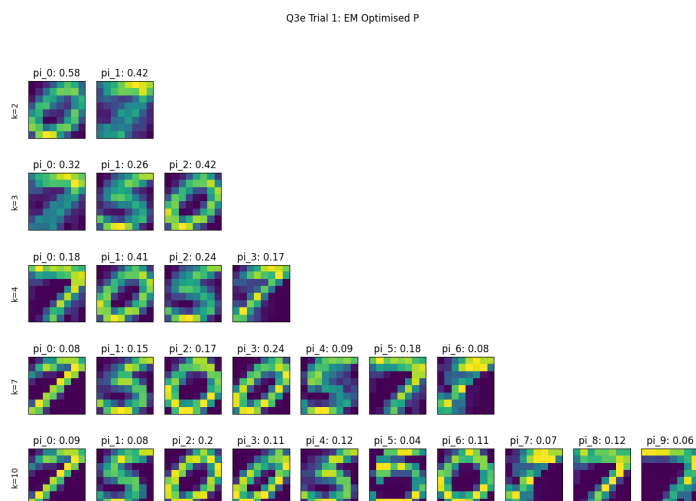

Figure 8: EM optimised parameters: Trial 1

Figure 9: EM optimised parameters: Trial 2

Figure 10: EM optimised parameters: Trial 3

For smaller k , we can visually see that we obtain very similar solutions (a 7 and a 0 for $k = 2$). However for higher K , we see that this may not always be the case. For Trial 2 of $k = 10$, we have three 5's whereas in Trial 4 we have two 5's. Interestingly, different clusters of the same digits can be different, representing different variants of the written digit (i.e. a slanted zero, a slightly slanted zero, and a symmetric zero).

Moreover, looking at the responsibilities of each mixture component, we can see that when k is relatively small they are relatively evenly distributed. However for $k = 7$ and especially $k = 10$, we can see some components have very small or zero probability (i.e. π_2 of trial 2). It will be unlikely for those components to represent very distinct clusters (i.e. the parameters for π_2 and π_9 are very similar in trial 2) This can be verified when we perform a TSNE visualisation of the responsibility vector for each of the images (Note that for $k = 2$, the responsibility vector is displayed). We can see that for large k , qualitatively the number of clusters no longer matches the k value, indicating that some clusters are redundant. For example for $k = 7$ and $k = 10$ we can only qualitatively see four or five clusters with TSNE.

Figure 11: TSNE Visualisation of Image responsibilities: Trial 0

Figure 12: TSNE Visualisation of Image responsibilities: Trial 1

Figure 13: TSNE Visualisation of Image responsibilities: Trial 2

Figure 14: TSNE Visualisation of Image responsibilities: Trial 3

Improvements to the model could include searching for an optimal k by maximising the log posterior with regularisation on the magnitude of k to balancing maximising log posterior with minimising model complexity. Additionally, adding a prior on the responsibility components can be helpful to ensure non-zero mixing components unlike the components visualised here. This could help promote more meaningful clusters as k increases.

[BONUS] Express the log-likelihoods obtained in bits and relate these numbers to the length of the naive encoding of these binary data. How does your number compare to gzip (or another compression algorithm)? Why the difference? [5 marks]

[BONUS] Consider the total cost of encoding both the model parameters and the data given the model. How does this total cost compare to gzip (or similar)? How does it depend on K ? What might this tell you? [5 marks]

Question 5

- (a) The formulae for the ML estimates of $P(s_i = \alpha | s_{i-1} = \beta) = \Psi(\alpha, \beta)$:

$$\Psi(\alpha, \beta) = \frac{N_{s_i, s_{i-1}}}{N_{s_{i-1}}}$$

where $N_{s_i, s_{i-1}}$ is the count of the number of occurrences of the pair (s_i, s_{i-1}) , where s_{i-1} is followed by s_i and $N_{s_{i-1}}$ is the number of occurrences of s_{i-1} .

Moreover, the stationary distribution ϕ can be calculated using the power method:

- (i) Initialise any $\phi_0 \in \mathbb{R}^{53 \times 1}$
- (ii) Repeat $\phi_{i+1} = \Psi \phi_i$
- (iii) Terminate when $\phi_{i+1} - \phi_i < \epsilon$

where $\Psi \in \mathbf{R}^{53 \times 53}$ containing the transition probabilities, $\Psi_{i,j} = P(\alpha_j | \alpha_i)$ where α_i is the i^{th} symbol and α_j is the j^{th} symbol, and ϵ is some small number indicating sufficient convergence of the distribution to be considered stationary. The function $\phi(\gamma)$ is simply the index of γ in the vector ϕ .

The transition matrix Ψ :

[illegible]

(Apologies for the tiny font, latex was being difficult)

- (b) The latent variables $\sigma(s)$ for different symbols s are not independent. This is because by choosing an encoding for one symbol $e = \sigma(s)$, the encoding for a second symbol $\sigma(s')$ cannot be e . We have 53 symbols but only 52 degrees of freedom, because once we have defined the encoding for 52 symbols, the encoding for the 53rd symbol cannot be chosen. Thus, there exists a dependence between the symbols for a given σ .

The joint probability of the encrypted text $e_1 e_2 \dots e_n$ given σ :

$$P(e_1, e_2, \dots, e_n | \sigma) = \phi(\gamma = \sigma^{-1}(e_1)) \prod_{i=2}^n \psi(\alpha = \sigma^{-1}(e_i), \beta = \sigma^{-1}(e_{i-1}))$$

because σ is the encoding function, mapping a symbol s into the encoded symbol e , we require σ^{-1} the decoding function mapping the encoded symbol e back to s .

- (c) The proposal probability $S(\sigma \rightarrow \sigma')$ depends on the permutations of σ and σ' . Our proposal generating process restricts us to choose a proposal σ' that differs from σ only at *two* spots:

$$\sigma'(s^i) = \sigma(s^j)$$

$$\sigma'(s^j) = \sigma(s^i)$$

for any two symbols s^i and s^j of the 53 possible symbols ($s^i \neq s^j$).

Therefore, if the above doesn't hold for σ' , $S(\sigma \rightarrow \sigma') = 0$. From σ there are $\binom{53}{2}$ possible proposal σ' 's with the above property. Because we are assuming a uniform prior distribution over σ 's, the transition probability of a σ' that satisfies the above property is $S(\sigma \rightarrow \sigma') = \frac{1}{\binom{53}{2}}$.

The MH acceptance probability is given as:

$$A(\sigma \rightarrow \sigma' | \mathcal{D}) = \min\left\{1, \frac{S(\sigma' \rightarrow \sigma)P(\sigma' | \mathcal{D})}{S(\sigma \rightarrow \sigma')P(\sigma | \mathcal{D})}\right\}$$

because $S(\sigma \rightarrow \sigma')$ is the conditional transition probability of σ' given σ and \mathcal{D} is our encrypted text e_1, e_2, \dots, e_n .

$S(\sigma \rightarrow \sigma') = S(\sigma' \rightarrow \sigma)$ for all σ and σ' that differ only at two spots because the probability in this case will always be $\frac{1}{\binom{53}{2}}$, we can simplify:

$$A(\sigma \rightarrow \sigma' | \mathcal{D}) = \min\left\{1, \frac{P(\sigma' | \mathcal{D})}{P(\sigma | \mathcal{D})}\right\}$$

From Bayes' Theorem:

$$P(\sigma | \mathcal{D}) = \frac{P(\mathcal{D} | \sigma)P(\sigma)}{\sum_{\sigma'} P(\mathcal{D} | \sigma')P(\sigma')}$$

We are assuming a uniform prior for σ , so $P(\sigma)$ is a constant and we can simplify further:

$$A(\sigma \rightarrow \sigma' | \mathcal{D}) = \min\left\{1, \frac{P(\mathcal{D} | \sigma')}{P(\mathcal{D} | \sigma)}\right\}$$

This is the acceptance probability for a given proposal σ' . The expression for $P(\mathcal{D} | \sigma)$ is $P(e_1, e_2, \dots, e_n | \sigma)$ described in the previous part.

(d) Reporting the current decryption of the first 60 symbols after every 100 iterations:

To help with chain initialisation, 10000 different σ 's were randomly and independently sampled. The σ providing the best log-likelihood was chosen as the starting point for the MH chain and algorithm was then run for 10000 iterations. Moreover, ten different trials were performed, where the trial with the best log-likelihood is displayed.

The Python code for the MH sampler:

src/solutions/q5.py

- (e) When some values of $\Psi(\alpha, \beta) = 0$, this affects the ergodicity of the chain. An ergodic chain is one that is irreducible (i.e. all possible transitions between symbols have probability greater than zero). If $\Psi(\alpha, \beta) = 0$, this means that there is zero probability that β will transition to α , breaking our definition. To restore ergodicity, we can add a small transition probability between all symbols of the chain. This essentially acts as a prior, stating that the probability of a symbol to transition to any other symbol (including itself) should never be zero.
- (f) Analyse this approach to decoding. For instance, would symbol probabilities alone (rather than transitions) be sufficient? If we used a second order Markov chain for English text, what problems might we encounter? Will it work if the encryption scheme allows two symbols to be mapped to the same encrypted value? Would it work for Chinese with > 10000 symbols? [13 marks]

If we were to use symbol probabilities alone for decoding, the joint probability would be:

$$P(e_1, e_2, \dots, e_n | \sigma) = \prod_{i=1}^n P(\sigma^{-1}(e_i))$$

the product of the likelihoods of the decoded letters. In this case, the optimal decoding would simply replace the most frequent symbols in the encrypted message with the most frequent symbols in the training text. This is much more difficult because each letter is assumed to be independent of its neighbours. For a first order Markov chain, we exploit the structure of language by considering pairs of letters. Assuming that as the training text size approaches infinity and the size of the encrypted message also approaches infinity, that the two will have the same symbol frequency and that the probability of each symbol is unique, (i.e. two different decodings can't have the same likelihood), then using symbol probabilities alone should theoretically work. However, in practise we would unlikely to be able to make these assumptions about symbol frequencies from the size of our training set and encrypted message.

A second-order chain should also work in theory. However, this approach is probably practically more difficult for finding a suitable decoding. This is because our transition matrix would contain N^3 , where N is the number of symbols, to account for all possible second order transitions. Our training text would need to increase quadratically to maintain the same ratio of possible transitions to example transitions (number of second order transitions in a text of length N is $N - 2$ and third order its $N - 3$).

For an encryption scheme where two symbols map to the same encrypted value:

$$\exists \alpha, \beta, \sigma(\alpha) = \sigma(\beta), \alpha \neq \beta$$

this approach can become much more complicated. Our $\sigma^{-1}(e)$ is ill-defined, and therefore how we computing the joint probability of the encrypted text is no longer immediately clear. Moreover, generating proposal encodings is not as simple as swapping the encryption for two symbols. This is because we do not know which two symbols map to the same encrypted symbol and simply swapping would preserve the same collision mapping of the current encoding. Overall, many changes would need to be made to the approach to accommodate for these complications. It is not immediately obvious how current approach could work for this case.

If we used this approach for Chinese with ≥ 10000 symbols, we would be attempting to solve the same problem but with $N \geq 10000$ instead of $N = 53$. Similar to the second order Markov chain, although this is theoretically possible, it would require a transition matrix of size $\geq 10000^2$ which is quite impractical. An alternative set up could be with using Chinese phonetics, for which there are likely much fewer than 10000, however this would require a mapping from a phonetic to an encrypted phonetic.

Question 7

- (a) To find the local extrema of the function $f(x, y) = x + 2y$ subject to the constraint $y^2 + xy = 1$, first we define $g(x, y)$:

$$g(x, y) = y^2 + xy - 1$$

where $g(x, y) = 0$ is an equivalent representation of the given constraint.

We can therefore construct the optimisation problem:

$$\min_{\mathbf{x}} f(\mathbf{x})$$

such that $g(\mathbf{x}) = 0$ and $\mathbf{x} := [x, y]^T$.

We can calculate $\nabla f(\mathbf{x})$:

$$\nabla f(\mathbf{x}) = \left[\frac{\partial}{\partial x}(x + 2y), \frac{\partial}{\partial y}(x + 2y) \right]^T$$

$$\nabla f(\mathbf{x}) = [1, 2]^T$$

and calculating $\nabla g(\mathbf{x})$:

$$\nabla g(\mathbf{x}) = \left[\frac{\partial}{\partial x}(y^2 + xy - 1), \frac{\partial}{\partial y}(y^2 + xy - 1) \right]^T$$

$$\nabla g(\mathbf{x}) = [y, 2y + x]^T$$

Solving the constraint optimisation problem with Lagrange multipliers, we set up the equations:

$$\nabla f(\mathbf{x}) + \lambda \nabla g(\mathbf{x}) = \mathbf{0}$$

and

$$g(\mathbf{x}) = 0$$

Giving us the three equations:

$$1 + \lambda y = 0$$

$$2 + \lambda(2y + x) = 0$$

$$y^2 + xy - 1 = 0$$

Substituting $y = \frac{-1}{\lambda}$ from the first equation into the second equation:

$$2 + \frac{-1}{\lambda}(2y + x) = 0$$

$$\frac{-x}{y} = 0$$

We see that $x = 0$. Solving for y in our third equation with $x = 0$:

$$y^2 - 1 = 0$$

We see that $y = \pm 1$ and from the first equation $\lambda \mp 1$.

The local extrema are $(x = 0, y = 1)$ when our $\lambda = -1$ and $(x = 0, y = -1)$ when our $\lambda = 1$.

(b)

(i) Given that $g(a) = \ln(a)$, we want to transform this to the form $f(x, a) = 0$:

$$x = \ln(a)$$

$$\exp(x) - a = 0$$

Thus,

$$f(x, a) = \exp(x) - a$$

(ii) We know that for Newton's method's

$$x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)}$$

where $f(x_n) = \exp(x_n) - a$

We can calculate:

$$f'(x) = \frac{\partial f(x, a)}{\partial x} = \exp(x)$$

Assuming we can evaluate $\exp(x)$, our update equation:

$$x_{n+1} = x_n - \frac{\exp(x_n) - a}{\exp(x_n)}$$

Simplifying:

$$x_{n+1} = x_n + \frac{a}{\exp(x_n)} - 1$$

Question 8

(a) For:

$$\sup_{\{\mathbf{x} \in \mathbb{R}^n\}} R_A(\mathbf{x})$$

where $R_A(\mathbf{x}) = \frac{\mathbf{x}^T \mathbf{A} \mathbf{x}}{\|\mathbf{x}\|^2}$, we want to show that a maximum is attained.

To do this, we will show the above optimisation can be equivalently formulated:

$$\sup_{\{\mathbf{x} \in \mathbb{R}^n \mid \|\mathbf{x}\|=1\}} R_A(\mathbf{x})$$

We begin by considering any $\mathbf{w} \in \mathbb{R}^n$ and let $\mathbf{x} = \frac{\mathbf{w}}{\|\mathbf{w}\|}$. Because $\|\mathbf{x}\| = 1$ we can substitute:

$$\sup_{\{\frac{\mathbf{w}}{\|\mathbf{w}\|} \in \mathbb{R}^n \mid \|\frac{\mathbf{w}}{\|\mathbf{w}\|}\|=1\}} R_A(\mathbf{x}) = \sup_{\mathbf{x} \in \mathbb{R}^n \mid \|\mathbf{x}\|=1} \frac{\mathbf{w}^T \mathbf{A} \mathbf{w} \|\mathbf{w}\|^2}{\|\mathbf{w}\|^2 \mathbf{w}^T \mathbf{w}}$$

where $\|\mathbf{x}\|^2 = \mathbf{x}^T \mathbf{x}$.

The set $\{\frac{\mathbf{w}}{\|\mathbf{w}\|} \in \mathbb{R}^n \mid \|\frac{\mathbf{w}}{\|\mathbf{w}\|}\| = 1\}$ holds for all $\mathbf{w} \in \mathbb{R}^n$ so we can rewrite:

$$\sup_{\{\mathbf{w} \in \mathbb{R}^n\}} \frac{\mathbf{w}^T \mathbf{A} \mathbf{w} \|\mathbf{w}\|^2}{\|\mathbf{w}\|^2 \mathbf{w}^T \mathbf{w}}$$

We can simplify the expression:

$$\begin{aligned} & \sup_{\{\mathbf{w} \in \mathbb{R}^n\}} \frac{\mathbf{w}^T \mathbf{A} \mathbf{w}}{\mathbf{w}^T \mathbf{w}} \\ & \sup_{\{\mathbf{w} \in \mathbb{R}^n\}} R_A(\mathbf{w}) \end{aligned}$$

and recover our original optimisation problem by letting $\mathbf{x} = \mathbf{w}$, showing that it is equivalent to the supremum over the unit sphere. Assuming the set containing the unit sphere is compact, the extreme value theory of calculus states that $\sup_{\{\mathbf{x} \in \mathbb{R}^n \mid \|\mathbf{x}\|=1\}} R_A(\mathbf{x})$ is attained so equivalently $\sup_{\{\mathbf{x} \in \mathbb{R}^n\}} R_A(\mathbf{x})$ is attained as required.

(b) We can now reformulate the optimisation as:

$$\sup_{\{\mathbf{x} \in \mathbb{R}^n \mid \|\mathbf{x}\|=1\}} \frac{\mathbf{x}^T \mathbf{A} \mathbf{x}}{\|\mathbf{x}\|^2}$$

But because $\|\mathbf{x}\| = 1$, we can equivalently write:

$$\sup_{\{\mathbf{x} \in \mathbb{R}^n \mid \|\mathbf{x}\|=1\}} \mathbf{x}^T \mathbf{A} \mathbf{x}$$

Thus, showing $\mathbf{x}^T \mathbf{A} \mathbf{x} \leq \lambda_1$ will be equivalent to showing $R_A(\mathbf{x}) \leq \lambda_1$ for $\|\mathbf{x}\| = 1$. We know that for all $\mathbf{x} \in \mathbb{R}^n$:

$$\mathbf{x} = \sum_{i=1}^n (\xi_i^T \mathbf{x}) \xi_i$$

so we can write:

$$\mathbf{x}^T \mathbf{A} \mathbf{x} = \left(\sum_{i=1}^n (\xi_i^T \mathbf{x}) \xi_i^T \right) \mathbf{A} \left(\sum_{i=1}^n (\xi_i^T \mathbf{x}) \xi_i \right)$$

Given that ξ_i are eigenvectors of \mathbf{A} corresponding to eigenvalues λ_i :

$$\mathbf{x}^T \mathbf{A} \mathbf{x} = \left(\sum_{i=1}^n (\xi_i^T \mathbf{x}) \xi_i^T \right) \left(\sum_{i=1}^n \lambda_i (\xi_i^T \mathbf{x}) \xi_i \right)$$

Given that the eigenvectors ξ_i form an orthonormal basis, we know that $\xi_i^T \xi_j = 0$ when $i \neq j$ and $\xi_i^T \xi_i = 1$ when $i = j$, so:

$$\mathbf{x}^T \mathbf{A} \mathbf{x} = \sum_{i=1}^n \lambda_i (\xi_i^T \mathbf{x})^2$$

We know that $\|\mathbf{x}\|^2 = 1$ so $\|\mathbf{x}\|^2 = \sum_{j=1}^n x_j^2 = \sum_{j=1}^n (\xi_j^T \mathbf{x})^2 = 1$. Thus the quantity $\sum_{i=1}^n \lambda_i (\xi_i^T \mathbf{x})^2$ is simply a weighted average of λ_i 's and we can write:

$$\mathbf{x}^T \mathbf{A} \mathbf{x} = \sum_{i=1}^n \lambda_i (\xi_i^T \mathbf{x})^2 \leq \lambda_1$$

where λ_1 is the largest eigenvalue of eigenvalues λ_i . Therefore, $R_A(\mathbf{x}) \leq \lambda_1$ as required.

(c) Given that $\lambda_j < \lambda_1 \forall j > k$ and $\mathbf{x} \in \text{span}\{\xi_{k+1}, \dots, \xi_n\}$, we can rewrite \mathbf{x} :

$$\mathbf{x} = \sum_{i=k+1}^n (\xi_i^T \mathbf{x}) \xi_i$$

From the same argument as (b) we can bound $\mathbf{x}^T \mathbf{A} \mathbf{x}$:

$$\mathbf{x}^T \mathbf{A} \mathbf{x} = \sum_{i=k+1}^n \lambda_i (\xi_i^T \mathbf{x})^2 \leq \max\{\lambda_{k+1}, \dots, \lambda_n\}$$

But given that the maximum eigenvalue λ_1 is not contained in $\{\lambda_{k+1}, \dots, \lambda_n\}$:

$$\max\{\lambda_{k+1}, \dots, \lambda_n\} < \lambda_1$$

and therefore,

$$R_A(\mathbf{x}) < \lambda_1$$

as required.
